Fusarium head blight (FHB), also known as scab or tombstone, is a disease of wheat, barley, oats and other small cereal grains and corn (Figure 1). It is caused by several species of *Fusarium*; however, *Fusarium graminearum* is the primary species involved. In 1999, *Fusarium graminearum* was declared a pest under the Alberta Agricultural Pests Act.

This disease reduces yield and grade and may also contaminate the grain with fungal toxins (mycotoxins). FHB is favoured by humid conditions during flowering and early stages of kernel development.

FHB is recognized in the field by the premature bleaching of infected spikelets and the production of orange, spore-bearing structures called sporodochia at the base of the glumes. During wet weather, there may be whitish, occasionally pinkish, fluffy fungal growth on infected heads in the field.

Diseased spikelets can contain visibly affected kernels. The grading term given to visibly affected wheat seeds is fusarium damaged kernels (FDK), whereas in barley, it is called fusarium mould (Figure 2).

Alberta is currently free of any outbreaks of fusarium head blight caused by *F. graminearum*. Trace levels of *F. graminearum* have been found in Alberta in a few instances, and actions have been taken to eliminate these traces. If this fungal disease were to become established in this province, it would have major economic consequences for Alberta’s cereal and animal feeding industries.
FDK in wheat are shrunken and typically chalky white, while fusarium mould on barley is an orange or black encrustation of the seed surface. Much of the severely infected wheat is poorly filled and may be blown out the back of the combine due to its low kernel weight. Grain infected after the flowering stage may be heavy enough to be harvested along with healthy grain, although most FDK will result from infections that occur during flowering.

The fungus may eventually kill the developing seed at about the soft dough stage. Symptoms of fusarium mould in barley or oats are usually sparse, making it difficult to tell if grain has been infected.

Why the concern about FHB?

Wheat and barley infected by FHB may contain mycotoxins such as deoxynivalenol (DON), also known as vomitoxin. As mycotoxins go, DON is one of the least toxic to animals but may result in reduced feed consumption or feed refusal. This toxin is produced primarily by *F. graminearum* and *F. culmorum*. Non-ruminants are the most sensitive to the presence of DON (Figure 3).

Fusarium fungi can produce DON levels as high as 30 parts per million (ppm) in wheat and barley. On average, 1 per cent FDK (if caused by *F. graminearum* or *F. culmorum*) will produce 1 ppm DON, although it can range from 0.5 to 4 ppm. Thus, 5 per cent FDK in wheat will give, on average, 5 ppm DON.

Some studies have shown that beef cattle can feed on grain that has up to 12 ppm DON, but calves may have problems at much lower contamination levels. Non-ruminants like hogs will tolerate 1 ppm, but pregnant animals or breeding stock may suffer even at this level. Dairy cows have been shown to tolerate 8 ppm DON without affecting milk yield. Calves, lambs and lactating ewes have no effects at 10 ppm or more. Adult cows, adult sheep and poultry can tolerate up to 15 ppm DON in feed grain. Agriculture and Agri-Food Canada guidelines are 1 ppm for swine, dairy cattle and horses and 5 ppm for growing beef cattle, sheep and poultry. The toxicity of DON is such that animals or humans do not die from ingesting it.

The Federal Health Protection Branch allows 2 ppm of DON in uncleaned soft white winter wheat and 1 ppm in uncleaned soft white spring wheat intended for infant foods. A suspicion of fusarium mould in malting barley can lead to rejection. Several malting companies have a zero tolerance for DON in barley.

Where is this disease a problem?

Outbreaks of FHB in wheat or barley and other grains generally occur in the more humid regions of North America. Over the last several years, FHB has been the most important cereal disease of the eastern Canadian prairies, eastern Canada, and the midwest US.
Using corn in rotation with small cereal grains has been shown to increase the problem, although corn is not an essential link in the disease cycle. All cereal and corn residue can help the fungus overwinter and will act as an inoculum source in the spring. Corn stubble can harbor huge amounts of *Fusarium* fungi that may infect small grain heads, causing fusarium head blight in barley and wheat.

Where FHB levels are high, mycotoxin problems are not unusual. Although FHB and FDK can occur in the western prairies, levels are usually very low and the causal species is usually not *Fusarium graminearum*. Grain from the western prairies can become mouldy from long-term weather exposure in the swath or by heating up after harvest, but this damaged grain will usually not contain DON since the causal species is rarely a DON producer. However, the grain may contain other compounds that could affect its suitability as feed.

How to minimize the FHB risk?

After an extensive public consultation process, the Province of Alberta developed the *Alberta Fusarium graminearum Management Plan*. This plan came into effect October 1, 2002, and specifies the provincial strategy for meeting the threat of this devastating disease, while still sustaining all sectors of the agriculture industry in Alberta.

The control strategies in this plan are enforced under the authority of the Alberta Agricultural Pests Act. The long-term goal of the management plan is to prevent the introduction and establishment of *F. graminearum* in Alberta until effective disease control measures for this pathogen are developed. It is expected that the most effective control of this disease will involve the development of resistant wheat and barley cultivars.

The prevention and control strategies presented in the management plan address the most likely avenues of introduction and establishment of *F. graminearum* in Alberta until effective disease control measures for this pathogen are developed. It is expected that the most effective control of this disease will involve the development of resistant wheat and barley cultivars.

The key components of the best management practices are enforcement of the plan in accordance with a number of best management practices. The seed testing requirement will allow low level infestations to be monitored for and caught early, before the outbreaks get out of control. Focusing entirely on seed produced outside the province ignores the real possibility of low level infections becoming established and spreading within the province. Testing Alberta-produced cereal seed represents an important early warning component of *F. graminearum* control.

Imported seed

All imported cereal seed also has to be treated with a fungicide seed treatment that is registered for control of seed-borne *Fusarium*. This step adds another level of protection against the possibility of low level infections in seed lots that test negative for the pathogen. It is highly recommended, but not required, that all seed produced in Alberta also be treated with a fungicide.

Feed grain

Feed grain represents a risk for introducing *F. graminearum* due to the sheer volume of feed grain that is brought into Alberta. The management plan recognizes this risk and requires that feed grain be handled responsibly in accordance with a number of best management practices. The key components of the best management practices are to ensure that all infected grain is fed to cattle and that spillage is avoided, with spilled grain cleaned up and composted.

It is known that *F. graminearum* on infected grain is killed during passage through the digestive system of cattle. Composting infected grain or crop residue (grass hay or straw) to reach a temperature of 60 to 70°C for two weeks will also kill any *F. graminearum* present in the grain or crop residue.

Infected grain must not be allowed to come in contact with the soil, which would allow *F. graminearum* to establish foothold in roadsides or fields. Unloading sites must be covered or equipped with drop socks and wind fences to ensure that grain does not blow onto adjacent soil. Trucks, or any vehicles, used to haul feed grain must be securely tarped. Trucks must be cleaned thoroughly at the unloading site and all remaining grain composted.

Feed grain cannot be stored in direct contact with the soil, nor can it be uncovered. Moisture contacting this grain can promote the growth and development of *F. graminearum*.

All things considered, it is recommended that producers buy *Fusarium*-free grain as this precaution greatly reduces the risk of introducing the pathogen. Recent experience has shown that *Fusarium*-free feed grain has been available to those who have insisted on grain that has been tested and found free of *F. graminearum*.
Hay and straw

Grass hay and straw from areas infested with *F. graminearum* can also carry the pathogen and should be handled in accordance with the best management practices for feed grain. Of the two products, grass hay represents a lower risk as the hay should all go through the cattle, which will kill any *F. graminearum* present.

Bedding straw represents a very high risk of spreading *F. graminearum* because imported straw will very likely have high levels of infection, and the practice of spreading bedding straw in fields can bring the pathogen in direct contact with the soil. If the bedding straw is not collected and composted in early spring, any *F. graminearum* present is in an excellent position to establish in the field.

In the field

The last line of defense occurs when *F. graminearum* infections are identified in cereal fields (Figure 4). Such an occurrence would trigger an eradication strategy where the crop is immediately ensiled or harvested, and the residue carefully managed and cultivated. The field would be taken out of cereal production for three years to allow the crop residue to degrade, resulting in the eradication of the pathogen. *Fusarium graminearum* does not survive in fields where the host material has degraded and is no longer present.

Experience has shown that it is possible to eradicate this pathogen from a field where it has begun to establish. Swift action is required, and the strategy will only be effective if merely a few fields become infected. Attempts to eradicate *F. graminearum* from a large number of infected fields over a wide area will not likely be successful.

The success of the Alberta *Fusarium graminearum* Management Plan depends on the effective participation of all players in Alberta’s agriculture industry. Any inconvenience or temporary hardship in complying with the control measures is a small price to pay when compared to the long-term loss that would be associated with an established *F. graminearum* problem.

Growing season

During the growing season, growers should check fields for the presence of this disease. Check for symptoms on cereal heads about three weeks after anthesis and in the grain at harvest. If *F. graminearum* is found, a rotation out of cereals should be considered, as should the planting of varieties least susceptible to the disease.

Unfortunately, varieties resistant to head blight are not available, but varieties and crop species do vary in their level of susceptibility. In general, the level of susceptibility decreases from durum wheat to CPS wheat to hard red spring wheat to barley and to oats.

Figure 4. Partial *Fusarium graminearum* infection of the head, the flowers in the bleached portion of the head are killed.

Currently, there is substantial activity involving the development of resistant cereal varieties both in Canada and the U.S. If producers are in areas where *F. graminearum* is present or they are concerned about FHB, they are encouraged to consult provincial crop variety guides for help in choosing varieties that are the least susceptible to this disease.

The Canadian Grain Commission (CGC) offers a grading service to producers who submit samples for grade, dockage and/or moisture analysis. This service requires a 1000 g (about 2 lbs.) representative sample and should be sent to their nearest CGC Service Centre. There is a fee for this service.
Testing grain

Several companies in western Canada, including the Canadian Grain Commission, offer DON testing services. Most of these sources will use a ‘quick’ test. The simplest tests are a ‘yes/no’ type, where the sample is judged to have more or less toxin than a chosen standard. A more sophisticated test will place the level between two chosen standards, without giving an exact number. The most precise, and somewhat more expensive quick test, will produce a number (in parts per million) for the toxin level in the sample (Figure 5).

Before choosing a testing lab, growers should decide what type of test result they require. The less exact the result required, the cheaper the test (usually). The quick tests can range from around $25.00 to $50.00. Ask if there is a discount for submitting several samples at once (if appropriate). Growers should ask if the company uses check samples to validate the tests, and if so, how often.

Cost should not be the sole reason for choosing one company over another. If the test result does not make sense to you (if, for example, you receive a high DON result but the wheat had little or no FDK), consider retesting the sample for DON and also perhaps having it tested for the presence or absence of DON-producing pathogens like Fusarium graminearum or Fusarium culmorum. In addition, you may want to consider seeking the advice of individuals familiar with mycotoxin testing in cereal grain.

In Alberta, DON has mainly been found in soft white spring wheat at relatively low levels. However, when handling FDK in grain, the dust may contain high levels of the fungus. Grain handlers should take all the same precautions they would if they were handling mouldy grain. These precautions could include using masks, goggles and protective clothing.

Figure 5. Fusarium graminearum infection in barley.

All tests will have a detection limit, below which the sample is said to have a non-detectable level of the toxin. In many of the most popular tests, this detection limit is 0.5 ppm. A more accurate but far more expensive type of test is one that uses sophisticated instrumentation. The detection limit of this type of test is about 0.05 ppm. As with any test, sampling is critical. Without a good, representative sample, test results will not accurately reflect the bulk from which the samples were taken.

To find out what is considered fusarium mould in barley, oats or other small grain cereals, please contact your nearest CGC Service Centre or Regional Centre or call 1-800-853-6705.

Testing for DON and *Fusarium* species

A number of laboratories can test for one or more of the following: DON level in harvested grain, general presence of *Fusarium* spp. on seed, grass hay or cereal straw, and the identification and differentiation of *Fusarium* spp., including *Fusarium graminearum*, infecting seed, grass hay and cereal straw.

For a list of laboratories that provide testing for mycotoxins or for the presence of *Fusarium* spp., please consult your local agricultural specialist, visit the Alberta Agriculture, Food and Rural Development website (www.agric.gov.ab.ca) or call the Alberta Ag-Info Centre at 1-866-882-7677.
**Fusarium graminearum Testing**

**Standardized test**
- Labs will use the Canadian Grain Commission Testing Method
- For straw and hay, labs will test the nodes
- Labs will only test for the presence/absence of *Fusarium graminearum*
- Labs will report the results back to the producer
